Abstract
In this work, we studied the chemical composition of argan oil (Argania spinosa (L.) Skeels, Sapotaceae) according to its mode of extraction, its origin of production and its altitude of the argan tree. To carry out this work, we compared the physico-chemical characteristics and the chemical composition of five samples differing by their mode of extraction or coming from different regions of Morocco. The study of the physicochemical characteristics of the five samples shows that the roasting of the almonds of the argan fruit appears as a parameter can increase the value of the peroxide index, decrease the percentage of α-tocopherol, and decrease the unsaponifiable rate in percentage. We also found that geographic origin can influence fatty acid values (behin C22:0). The results of the specific extinction and the refractive index do not give any precise information on the origin, the altitude and the method of extraction of argan oil. The study of the triglyceride fraction shows that the geographical origin of north-eastern Morocco can increase the value of triglyceride SOP (S: Stearic acid, O: oleic acid and P: Palmitic acid). Our study has demonstrated the high quality of argan oil extracted by mechanical pressing and the results of this work have helped support the commercialization of argan oil worldwide.

Keywords: Argan; Sapotaceae; Chemical Composition; Extraction Origin; Altitude; Marketing

Introduction
Morocco is one of the rare countries in North Africa to have a set of endemic ecosystems of remarkable biodiversity [1]. Argan (Argania spinosa (L.) Skeels, Sapotaceae) is a specifically Moroccan endemic [2], it is a rustic, xero-thermophilic species, which belongs to the tropical family of Sapotaceae, of which it is the only northern representative in the Mediterranean region (Algeria and Morocco) hence its marked endemism in this region [3]. It is a multi-use forest tree (forest-fruit-fodder) of great importance for the country both biologically, phylogenetic and ecological biodiversity as well as economically and socially. It has great medicinal and therapeutic benefits [4], thanks to the oil extracted from its fruits. In addition, it is highly sought after in cosmetics as a skin and hair conditioning agent. This ecosystem is based on a balance between resources and human exploitation, and also plays an important role in the fight against desertification and erosion [5]. Argan oil is the main product of the argan tree. It is extracted by women in an ancestral way and sometimes under very precarious conditions. The artisanal extraction of a liter of oil requires 20 hours of strenuous and intense work [6].

Traditionally extracted argan oil goes rancid after a few months. This is caused by several factors: the early dehulling of the fruit of the argan nut, the use of nuts rejected by goats, the precarious hygienic conditions during the extraction of artisanal oil, the packaging in bottles recycled and improperly cleaned and the use of water in the preparation of the oil. Argan oil is rich in oleic acid, which makes this oil particularly interesting in the regulation of cholesterol. In addition, argan oil is also rich in phytosterols which have an important activity and whose incorporation in a diet is supposed to offer cancer prevention [7]. Studies also show that polyphenols and phytosterols as well as a certain number of their derivatives have anti-tumor properties. Great efforts have been made to develop argan oil by improving its extraction technology and allowing forest users to benefit from this added value by creating cooperatives in the region that produces and sells argan oil [8].

This work had repercussions in the production region, both socio-economic and environmental. We are currently witnessing an international craze for this oil whose beneficial virtues have been demonstrated. However, good marketing of argan oil first requires
After the selection of five different samples by the mode of extraction or from different regions of Morocco. Argan oil is prepared by two different methods [7]:

- HPT: Argan oil is extracted by mechanical pressing from roasted almonds (HPT).
- HPNT: Argan oil is extracted by mechanical pressing from unroasted almonds (HPNT).

These oils are then analyzed in the Official Laboratory of Analysis and Chemical Research (LOARC) of Casablanca in Morocco, the physico-chemical characteristics and the chemical composition of all the samples are determined (fatty acid, sterols, triglycerides, tocopherols). The oils are analyzed according to the analysis methods already described in the literature [9].

Table 1 provides information on the origin and method of extraction of each sample of argan oil.

**Physicochemical Analyzes of Oils**

All analyzes were done in the Official Laboratory of Chemical Analysis and Research (LOARC) in Casablanca, Morocco. Determination of acidity [9], the peroxide value [10], the refractive index [11] of the absorbance in the ultraviolet [12], the saponification number [13], the unsaponifiable content [14] were measured according to the standardized methods of reference.

**Determination of Composition and Nature in Total Sterols**

Reference ISO 6799 [15]

**Operating Mode**

Weigh 2.5 g of argan oil and put into a 20 ml flask. 25 ml of a solution of potassium hydroxide (1N of ethanol) is added. The flask is heated under reflux for 30 minutes until the solution becomes clear. Then, 25 ml of distilled water is added to stop the reaction. The extraction of the unsaponifiable is carried out using 75 ml of hexane or petroleum ether. The organic phase is subjected to a series of washing with 15 ml of mixture (water/ethanol 95°) (90/10) in a separatory funnel. The hexane phase is transferred from the top of the ampoule into a 100 ml flask. After evaporation of the solvent using a rotary evaporator, the unsaponifiable material is recovered. The unsaponifiable agent, diluted with 300 µl of hexane or petroleum ether, is filtered on a silica column (25 cm × 4 mm). The HPLC device is equipped with a 205 nm-254 nm UV detector. The eluent is an isooctane/isopropanol (99/1) mixture whose flow rate is 1.2 ml/min. The duration of the analysis is 15 min, the sterol fraction recovered according to standard NF 12228 May 1999, is evaporated to dryness.
The sterols are converted to silylated derivatives (TMS) using a mixture of pyridine, hexamethyldisilazane (HMDS) and trimethylchlorosilane (TMCS), (9/1/1, v/v/v). The pyridine is evaporated to dryness and the silylated derivative is diluted with 60 μl of heptane or hexane. The TMS sterols are analyzed by gas chromatography (GC) on an apolar column (Chroma pack) (30m × 0.32mm, DI: 0.25μm, phase: CPSIL8CB). The HP Hewlett Packard 6890 GC Series Chromatograph is equipped with FID detector (T°: 300 °C). The carrier gas is nitrogen and its flow rates 1 ml/min (PE: 8.6 bar). The analysis is performed in temperature programming (200 °C up to 270 °C with a speed of 10 °C/min and an isotherm at 270 °C for 35 min).

Analysis of Tocopherols

Reference: NF ISO 5509 COFRAC code: CC30 (Normalization 2015)

Operating Mode

The tocopherols are analyzed by HPLC, on a silica column (25 cm × 4 mm), according to the AOCS method, official method CE8-89 revised 1990 updated 1992. The SHIMADZU brand device is equipped with a fluorimetric detector (excitation wavelength 290 nm - emission wavelength 330 nm). The elution is carried out with a mixture (isooctane/isopropanol) (99/1) with a flow rate of 1.2 ml/min during the analysis time (20 min).

Analysis of Fatty Acids

Reference: IUPAC No. 2.0 324 [16]

Operating Mode

The fatty acid methyl esters are analyzed by GC gas chromatography. The HP Hewlett Packard 6890 GC Series GC chromatograph is equipped with a divider (T: 240 °C) and a FID (T: 260 °C) injector. The carrier gas is nitrogen (PE: 12.4 bar). The analysis is carried out in temperature programming (140 °C to 200 °C with a speed of 10 °C / min and an isotherm at 200°C for 40 min) on a capillary column (polyethylene glycol) (30 m × 0.32 mm, DI: 0.25 μm).

Triglyceride Analysis

Reference: IUPAC No. 2.0 324 [16]

To 0.15 g of the argan oil are added 0.5 ml of methanolic KOH for HPLC (minimum 98%) and 10 ml of methanol in a 100 ml flask. The mixture is refluxed for 15 minutes until the solution is clear. Then 1 ml of heptane is added to the reaction mixture after cooling. The heptanic phase containing the methyl esters is transferred to a test tube and then a solution of sodium carbonate Na₂CO₃ is added. This neutralizes all free acids by giving sodium salts with a release of carbon dioxide. The methyl esters, which are in the organic phase, are removed using a 2 ml cone pipette and placed in a test tube. The methyl esters undergo a series of washing20ml are taken from the esters, which are placed in a tube of nominal capacity of 2 ml and then filled with heptane.

The fatty acid methyl esters are analyzed by GC gas chromatography. The HP Hewlett Packard 6890 GC Series GC chromatograph is equipped with a divider (T: 240 °C) and a FID (T: 260 °C) injector. The carrier gas is nitrogen (PE: 12.4 bar). The analysis is carried out in temperature programming (140 °C to 200 °C with a speed of 10 °C / min and an isotherm at 200°C for 40 min) on a capillary column (polyethylene glycol) (30 m × 0.32 mm, DI: 0.25 μm).

Results

Analysis of Physico-Chemical Characteristics

Table 2 and Figure 1 shows the results of the acidity value, the unsaponifiable rate, the saponification index and the specific extinction values at 270 nm (k270). All the acidity values observed are less than 1%. This result shows that argan oil is characterized by low acidity compared to other vegetable oils (acidity of olive oil ≤ 2%) [17]. The acidity of samples 1 and 2 (0.33%, 0.50% respectively) (belonging to the same batch of Tidzi) is higher compared to other samples such as 4.5, (0.28%, 0.14 respectively) (belonging to different lot). These results suggest that the origin may influence the acidity values of argan oil. Roasting also appears as a parameter influencing the acidity value of argan oil (sample 1 and 2). The acidity value of sample 3 is higher compared to that of other samples. This result can be linked to the geographic origin of the sample because this sample comes from the higher elevation lot (1532m). The unsaponifiable rate of argan oil is less than 0.8% (for virgin olive oil, it is less than or equal to 1.50%) [18]. Argan oil extraction technology can influence the level of unsaponifiable matter in argan oil. Indeed, the unsaponifiable rate of sample 1 obtained by extraction by mechanical pressing from roasted almonds is lower (0.55%) than that which is prepared by mechanical press from non-roasted almonds (0.71%).
The argan oil saponification index (Table 2) was found between 180.0 and 199.0. For virgin olive oil, it is between 180 and 198\(^\text{[17]}\). The study of this work shows a great variation between the values of the saponification index of argan oil extracted from roasted and non-roasted almonds of the same batch (Tidzi). Indeed, samples 2 have a low saponification value (180). The specific extinction of argan oil was determined at 270 nm. In general, the values found are higher than that of olive oil, they vary between 0.228 and 0.426 for argan oil. The peroxide index results for the 5 samples of argan oil. For all samples, a peroxide index lower than that required for virgin olive oil was observed. The peroxide index in sample 1 is higher. Indeed, this sample is taken from a lot nearest the Atlantic Ocean and at the same time is extracted from roasted almonds. This result clearly indicates that some components of argan oil are extremely sensitive to oxidation.

The high peroxide content is observed for sample 1. This is probably related to the extraction method, the hygienic and extraction conditions and the use of water in the preparation of the oil and also related to the geographic location. The determination of the peroxide index seems to be a critical measure for the evaluation of the quality of argan oil. The determination of the refractive index, in general, is used for a quick and reliable verification of the purity of a substance. Both the refractive index and the density depend on the chemical composition of the oil and its temperature. It grows with the establishment and presence on fatty chains of secondary functions. The refractive index was determined at 20 °C. The results show that this index varies between 1.4667 and 1.4705.

The fatty acid composition of the different oils was determined after methylation of the oil and analysis of the methyl esters by gas chromatography on a capillary column. Table 3 and Figure 2 groups together the results obtained for the 5 samples.

### Analysis of Fatty Acids

Table 3: Fatty acid composition of samples 1 to 5 (in %)

---

**Figure 1:** The main physico-chemical constants of the 5 samples of argan oil studied
The fatty acid composition corroborates with data from the literature [19]. Argan oil contains 80% unsaturated fatty acids. It is of the oleic – linoleic type and contains between 29 to 35% of essential fatty acids: linoleic acid (29 to 34%) (Vitamin F). This acid is said to be essential because it cannot be synthesized by the body and must be provided by food. Unsaturated fatty acids play an essential role in the prevention of cardiovascular disease and the omega 6 family (such as linoleic acid) is essential for the growth of the child [20]. Its oleic acid content makes argan oil particularly interesting in regulating cholesterol. The other fatty acids present are: myristic acid C14: 0 (0.10 to 0.15%), palmitic C16: 0 (11 to 13%) and stearic C 18: 0 (5 to 7%). The percentage of linolenic acid (C18: 3) in argan oil does not exceed 0.1%. Note the presence in argan oil of long chain fatty acids such as C20:0 (0.4%), C20:1 (0.5%), and C22:0 (0.1%).

No significant variation was observed between the different samples. Sample 3 contains a higher percentage of behinic acid (C22:0) (0.38%). On the other hand, this percentage does not exceed 0.1% for all the other samples, this sample is prepared from argan almonds gathered in the Benaiznassen plantation. These variations can be considered useful markers to ascertain the geographical origin of argan oils. No major significant variation was observed between samples. This demonstrated that the origin and the geographical process cannot influence the dietary qualities of argan oil. These results agree with those reported by [21,22] which showed that climatic conditions have no marked influence on the fatty acid composition of the oils of argan fruit from different localities.

**Trans Fatty Acid Analysis**

The trans fatty acid composition of the different oil samples was determined after methylation of the oil and analysis of the methyl esters by gas chromatography. Table 4 groups together the results obtained for the 5 samples. It appears from this result that the percentage of trans oleic and linoleic acid (C18: 1 and C18: 2), (elaidic acid) in argan oil is low and varies between 0.01% and 0.02%. The results are similar to those found for olive oil [17]. The presence of trans fatty acids in “virgin” argan oils, suitable for consumption, is an indication of the fraudulent presence of refined oil. For this reason, the trans fatty acid content has been limited by the standard to 0.05% for both elaidic acid and the sum of the trans isomers of linoleic and linolenic acids.

Table 4: Composition of trans fatty acids in samples 1 to 5

**Triglyceride Analysis**

The triglycerides of the different argan oil samples analyzed by high performance liquid chromatography are grouped in Table 5. Analysis of the triglyceride fraction of argan oil by HPLC allowed the separation of the individual triglycerides. We note the predominance of triglycerides LLO (12 to 14%), LOO (13 to 16%), LOP (14%), OOO (11 to 14%) and POO (15 to 16%). It is also noted that the oleic and linoleic acids occupy most of the Sn-2 position. Our results are in agreement with the data in the literature [17] which indicate that the triglycerides LLL, LLO, LOO, LOP, OOO and POO are predominant in argan oil. Samples 3 has a high percentage of triglycerides SOP (4%) this result clearly shows that the geographical location or the origin of the argan fruit can influence the chemical compositions.
Sterol Analysis

The sterol composition of the various argan oil samples was determined by gas chromatography after silylation of the sterol fraction. The latter is obtained by fractionation of the unsaponifiable matter of argan oil by HPLC on a normal phase. This analysis was carried out in the presence of an internal witness: 0.2% α-cholestanol in chloroform. The various sterols encountered were identified by gas chromatography coupled to mass spectrometry and by comparison with data from the literature [24]. Their individual and total assay was possible by GPC using an internal standard: α-cholestanol 0.2% in chloroform. Table 6 and Figure 3 summarizes the results obtained for the 5 samples selected. The total sterol content of all samples of argan oil ranges from 130 to 206mg / 100g of fat. This is not negligible compared to other seed and olive oils. The sterolic composition is in accordance with data from the literature [17]. They are essentially Δ-7-stigmasterols. The main products are schottenol (or Δ-7-stigmasterol) and spinasterol. Their proportion varies respectively between 42 and 48%, and 34 and 42%.

Table 6: Composition in sterols of samples 1 to 5 (mg / 100g)
Campest: Δ5-campesterol; 8.22 Stigma: Stigmasta-8, 22-diene-3β-ol; Spinast: spinasterol; Schott: schottenol; Stigma 7.24: stigmasta-7,24-diene-3β-ol

Schottenol and spinasterol are rarely found in vegetable oils and are characteristic of this oil. Two minority sterols were identified on the basis of their mass spectrum obtained by GC / MS and by comparison with data from the literature [24]. These are stigmast-8,22-diene and stigmasta-7,24-28-diene (or Δ-7-avenasterol). Their proportion varies between 2.6% and 6.9% of the mixture of total sterols. We find that the content of campesterol in argan oil is very low (0.3%) compared to other seed oils and olive oil. This parameter can be taken as a marker to detect adulteration of argan oil. We found that the percentage of total sterols is higher for the sample extracted from unroasted almonds (2 to 1). The variation in the sterol composition of the different samples is not significant.
Tocopherol Analysis

The tocopherols were analyzed by HPLC on a column in the normal phase, directly from vegetable oil without saponification. They were identified by comparison of their chromatogram with controls injected under the same conditions. Their dosage was possible by the use of α-tocopherol. The results obtained are grouped in Table 7 and Figure 4. Argan oil is richer in tocopherol (633 to 775 mg / kg) than olive oil (50 to 150 mg / kg) and than hazelnut oil (300 to 550 mg / kg).

Figure 4: Composition of tocopherols in samples 1 to 5 (mg/kg)

Tocopherols have vitamin E activity. This vitamin is a powerful antioxidant that captures free radicals and neutralizes destructive oxidation [25]. Our study shows that our samples are rich in γ-tocopherol (80 to 90%). Tocopherols are natural antioxidants, gamma tocopherol has the highest antioxidant power. Rich in gamma tocopherol, argan oil is a valuable nutraceutical. Tocopherols (vitamin E) and polyphenols are natural antioxidants. These play an essential role in the prevention of several diseases [26], because they are anti-free radicals. We found that samples 5, have a low content of total tocopherols (633 mg / kg). The roasting of almonds has an influence on total tocopherols. Indeed, the oils extracted from unroasted almonds have a higher total α-tocopherol content compared to the samples extracted from roasted almonds (sample 1 versus 2).

Discussion

As part of the development of argan oil, we conducted a comparative study of the different physico-chemical parameters of argan oil according to its mode of extraction and its origin of production. To carry out this work, we selected 5 samples of argan fruit located in different geographical localities of Morocco and extracted in different ways (by mechanical pressing from roasted and non-roasted almonds). The study of the physico-chemical characteristics shows that all the acidity values of argan oils are less than 1.40%. This result shows that argan oil is characterized by low acidity compared to other vegetable oils (acidity of the olive oil ≤2%). Our study shows that roasting appears as a parameter influencing the acidity value of argan oil. This is because the acidity value is higher in argan oil samples prepared from unroasted almonds. We also found that the argan oil sample from Tamanar batch had a higher acidity value compared to the samples. This finding suggests that geographic origin may influence acidity values.

The results concerning the unsaponifiable rate shows that argan oil is characterized by a low unsaponifiable rate (the unsaponifiable of the argan oil ≤0.81%) (unsaponifiable of the Olive oil ≤1.50%) [27]. Argan oil extraction technology can influence the unsaponifiable level of argan oil. In fact, the level of unsaponifiable matter in the sample prepared from roasted almonds is lower (0.56%) than that prepared from non-roasted almonds. Our study also shows that the roasting and the origin of the argan fruit have an influence on the reduction of this parameter (sample 1 and 2). Analysis of the peroxide index shows that the sample of argan oil extracted from roasted almonds has a higher peroxide content compared to sample 2 (same batch). The determination of the peroxide index seems to be a critical measure for the evaluation of the quality of argan oil. The specific extinction and the refractive index give no precise information on the origin and the method of extraction of argan oil.
Analysis of fatty acids shows that argan oil contains 80% unsaturated fatty acids. It is of the oleic – linoleic type and contains between 29 to 35% of essential fatty acids: linoleic acid (29 to 34%) (Vitamin F). Its oleic acid content makes this oil particularly interesting in regulating cholesterol. Our results show that the percentage of behenic acid (C22:0) is higher in the sample which was prepared from the argan almonds gathered in the Benaiznassen plantation. These variations can be considered useful markers to ascertain the geographical origin of argan oils. Sterol analysis shows that the total sterol levels of argan oil vary between 130 to 206mg / 100g of fat. The sterolic composition consists essentially of Δ-7-stigmasterols. The main products are schottenol (or Δ-7-stigmasterol) and spinasterol. It is noted that schottenol and spinasterol, which are very rare in vegetable oils, can be a parameter for the detection of adulteration of this oil. Two minority sterols were identified on the basis of their mass spectrum obtained by GC / MS. These are stigmast-8,22-diene and stigmasta-7,24,28-diene (or Δ-7-avenasterol).

The sterol composition does not show any significant variation. These results agree with those reported in the literature [28]. The sterol composition does not show any significant variation. These results agree with those reported in the literature. Argan oil is richer in tocopherols (633 to 775 mg / kg) than olive oil (50 to 150 mg / kg) and hazelnut oil (300 to 550 mg / kg). The results for tocopherols show that the extraction method and roasting can influence the composition of tocopherols. In contrast, the sample obtained from roasted almonds has a lower content of total a-tocopherols. Roasting decreases the total a-tocopherol content [17].

Analysis of the triglyceride fraction of argan oil allowed the separation of individual triglycerides. We note the predominance of triglycerides LLO (12% -14%), LOO (13% -15%), LOP (14%), OOO (12% -14%), and POO (14% -17%) in l'Argan Oil. These triglycerides represent approximately 73% of each fraction of triglycerides in argan oil. The triglyceride results do not give any specific information on the geographical origin and the extraction process of the argan fruit [29,30].

Conclusion
In this work we have studied the chemical composition of argan oil (Argania spinosa (L.) Skeels, Sapotaceae) according to its mode of extraction and its origin of production. To carry out this work, we compared the physico-chemical characteristics and the chemical composition of 5 samples differing by their mode of extraction or coming from different regions of Morocco. The results of this work show that the extraction method and the origin of the fruit of the argan tree can influence the peroxide index, the rate of unsaponifiable matter, fatty acids (including behenic: C22:0), the content of a-tocopherol and triglycerides (SOP). Our study has demonstrated the high quality of argan oil extracted by mechanical pressing and the results of this work have helped support the commercialization of argan oil worldwide.

Acknowledgments
The author would like to thank my fellow plant chemistry lab colleagues for their invaluable help and especially Mr. Mohamed Greih. To all the people who contributed directly or indirectly to the realization of this work, I send them my warmest thanks.
